

## CHAPTER 3

*2D MoS<sub>2</sub>/MnIn<sub>2</sub>S<sub>4</sub> hetero-  
interface with improved  
interfacial charge carrier  
transfer for photocatalytic  
H<sub>2</sub>O<sub>2</sub> production*

### 3.1 INTRODUCTION

In recent decades, a wide range of photocatalysts have been explored for H<sub>2</sub>O<sub>2</sub> production. Notable examples include titanium dioxide (TiO<sub>2</sub>)-based photocatalysts [11], carbon nitride (g-C<sub>3</sub>N<sub>4</sub>)-based photocatalysts [91,92], transition metal complexes [93], transition metal sulfides [36,94], and bismuth (Bi)-containing semiconductors [95]. Among these, metal sulfides have attracted significant interest in photocatalysis due to their tunable band gaps, favorable electronic structures, and abundant active sites [96].

In this context, MoS<sub>2</sub>, a typical layered transition metal dichalcogenide, has attracted significant attention due to its low cost, large surface area, strong visible light response, tunable bandgap structure, and favorable photocatalytic performance [97,98]. In particular, exfoliated or few-layered MoS<sub>2</sub> nanosheets with a 2D structure have emerged as promising photocatalysts. The unique optical and electronic properties of 2D MoS<sub>2</sub> contribute to better photoresponse and charge separation in photocatalysts [99]. As the number of layers decreases, MoS<sub>2</sub> exhibits enhanced properties that improve its photocatalytic performance [100,101]. To date, several studies have reported significant enhancements in photocatalytic activity using few-layer MoS<sub>2</sub> heterojunction composites, including In<sub>2</sub>S<sub>3</sub>/MoS<sub>2</sub> [102], CdS/MoS<sub>2</sub> [103], MoS<sub>2</sub>/rGO/CdS [104], WS<sub>2</sub>-MoS<sub>2</sub> [105], MoS<sub>2</sub>/g-C<sub>3</sub>N<sub>4</sub> [106], and MoS<sub>2</sub>/Mn<sub>0.2</sub>Cd<sub>0.8</sub>S [107]. These heterostructured photocatalysts, which couple 2D MoS<sub>2</sub> with other semiconductors, facilitate enhanced separation of photogenerated charge carriers and broaden solar light absorption. Composite formation effectively suppresses the recombination of charge carriers, thereby improving overall photocatalytic efficiency.

On the other hand, ternary chalcogenide AB<sub>2</sub>X<sub>4</sub> semiconductors have recently been recognized for their significant potential as visible-light-active photocatalysts, owing to

their tunable optical properties, unique electronic structure, narrow band gaps, and chemical photostability [108,109]. Among them, MnIn<sub>2</sub>S<sub>4</sub> stands out as an ideal photocatalyst due to its appropriate band gap for visible light absorption and the high reduction potential of its conduction band electrons. Chen et al. recently developed 2D/2D g-C<sub>3</sub>N<sub>4</sub>/MnIn<sub>2</sub>S<sub>4</sub> Z-scheme heterostructured photocatalysts for H<sub>2</sub> production and antibiotic degradation. Their study showed that heterostructure formation significantly enhanced visible light absorption and promoted efficient interfacial charge separation, resulting in superior photocatalytic performance compared to pristine g-C<sub>3</sub>N<sub>4</sub> and MnIn<sub>2</sub>S<sub>4</sub> [110]. Similarly, Song et al. fabricated Cu<sub>7</sub>S<sub>4</sub>/MnIn<sub>2</sub>S<sub>4</sub> semiconductor heterostructures using a simple oil bath and hydrothermal method. The nanocomposite, featuring ultra-thin 2D nanosheets and Cu<sub>7</sub>S<sub>4</sub> nanoparticles uniformly distributed on MnIn<sub>2</sub>S<sub>4</sub>, exhibited a photocatalytic hydrogen evolution rate of 13.81 μmol h<sup>-1</sup>, nearly 18 times higher than pure MnIn<sub>2</sub>S<sub>4</sub>. The enhanced performance was attributed to the forming of a p-n heterojunction that suppressed electron-hole recombination [111]. Deng et al. designed and constructed a MnIn<sub>2</sub>S<sub>4</sub>/WO<sub>3</sub> (Yb, Tm) photocatalytic system, incorporating a Z-scheme heterojunction to regulate spatial charge separation and improve light absorption through Yb<sup>3+</sup> and Tm<sup>3+</sup> doping. The system was evaluated for H<sub>2</sub>O<sub>2</sub> production, showing remarkable activity, producing 37.2 and 8.8 times more H<sub>2</sub>O<sub>2</sub> than WO<sub>3</sub> and MnIn<sub>2</sub>S<sub>4</sub>, respectively [112]. However, there are no prior reports on the development of a 2D/2D MoS<sub>2</sub>/MnIn<sub>2</sub>S<sub>4</sub> heterostructure photocatalyst.

In the current study, a heterostructure was constructed by combining few-layered MoS<sub>2</sub> with MnIn<sub>2</sub>S<sub>4</sub>, effectively integrating the advantages of both materials. This combination exhibits strong visible-light absorption, a low recombination rate of photoinduced electron-hole pairs, and excellent photocatalytic activity. Herein, we design and develop a novel 2D MoS<sub>2</sub>/MnIn<sub>2</sub>S<sub>4</sub> heterostructure photocatalyst through a green

## **CHAPTER 3: 2D MoS<sub>2</sub>/MnIn<sub>2</sub>S<sub>4</sub> hetero interface with improved interfacial charge carrier transfer for photocatalytic H<sub>2</sub>O<sub>2</sub> production**

---

hydrothermal process. The small petals of MnIn<sub>2</sub>S<sub>4</sub> were embedded on ultrathin 2D MoS<sub>2</sub> nanosheets, forming a well-integrated heterostructure (Scheme 3.1). The 2D morphology of MnIn<sub>2</sub>S<sub>4</sub> and MoS<sub>2</sub> enhances interfacial contact and facilitates efficient charge transfer between the two components. Various characterization techniques, including X-ray diffractometer (XRD), scanning electron microscope (SEM), transmission electron microscope (TEM), diffuse reflectance spectroscopy (DRS), photoluminescence (PL), contact angle, and electrochemical measurements, were employed to investigate the intrinsic relationship between the 2D hetero-interface structure and the significantly enhanced photocatalytic activity of the MoS<sub>2</sub>/MnIn<sub>2</sub>S<sub>4</sub> heterostructure. The photocatalytic activities of the resulting samples were assessed for H<sub>2</sub>O<sub>2</sub> production. The improved photocatalytic performance of the heterostructure systems can primarily be attributed to the Z-scheme mechanism. This mechanism effectively harnesses the strong reduction capability of photo-generated electrons in the conduction band of MnIn<sub>2</sub>S<sub>4</sub> nanosheets and the high oxidation capability of photo-generated holes in the valence band of 2D MoS<sub>2</sub> nanosheets. Furthermore, the mechanism of the H<sub>2</sub>O<sub>2</sub> production process has been thoroughly investigated. The pathway is elucidated through scavenger studies, and the reactive species involved in the photocatalytic H<sub>2</sub>O<sub>2</sub> production are identified based on confirmatory tests. This research will guide the future design of more versatile Z-scheme sulfide/chalcogenide heterostructure composites for H<sub>2</sub>O<sub>2</sub> production.

### **3.2 EXPERIMENTAL SECTION**

#### **3.2.1 Preparation of 2D MoS<sub>2</sub> nanosheets**

Pristine MoS<sub>2</sub> nanosheets were prepared through a one-step hydrothermal treatment[113]. Typically, one mmol of (NH<sub>4</sub>)<sub>6</sub>Mo<sub>7</sub>O<sub>24</sub>·4H<sub>2</sub>O and 30 mmol of NH<sub>2</sub>CSNH<sub>2</sub>

### **CHAPTER 3: 2D MoS<sub>2</sub>/MnIn<sub>2</sub>S<sub>4</sub> hetero interface with improved interfacial charge carrier transfer for photocatalytic H<sub>2</sub>O<sub>2</sub> production**

---

were dissolved in 35 ml of deionized water under vigorous stirring to form a homogeneous solution. The resulting mixture was then transferred to a 50 ml Teflon-lined autoclave and maintained at 210°C for 24 hours. After the reaction, the precipitates were allowed to cool naturally to room temperature, washed multiple times with water and absolute ethanol, and collected by ultracentrifugation at 25,000 rpm. The final products were dried at 60°C in a vacuum oven and stored for further use.

For the preparation of 2D MoS<sub>2</sub> nanosheets, 150 mg of the synthesized MoS<sub>2</sub> powder was initially dispersed in 80 mL of a mixed solvent of N-methyl pyrrolidone (NMP) and deionized water (50/50 (vol%)) in a stoppered conical flask[100]. The flask was then subjected to ultrasonic bath sonication for 120 minutes. The resulting suspension was left overnight, and the dispersion of exfoliated MoS<sub>2</sub> was isolated. Finally, the exfoliated MoS<sub>2</sub> was centrifuged at 25,000 rpm for 25 minutes, and the exfoliated MoS<sub>2</sub> powder was collected for further use.

#### **3.2.2 Preparation of MnIn<sub>2</sub>S<sub>4</sub>**

Firstly, 0.198 g of Manganese chloride tetrahydrate (1 mmol) and 0.537g of indium chloride tetrahydrate (2 mmol) were dissolved in 35 ml of deionized water under vigorous stirring for one hour. Then, 0.381g of thiourea (5 mmol) was added to the solution and stirred for two more hours. The suspension was transferred to a Teflon-lined stainless steel autoclave and heated at 210°C for 24 hours. Once the reaction was complete, the samples were allowed to cool naturally to room temperature, washed with ethanol, and dried in a vacuum oven [110].

#### **3.2.3 Synthesis of 2D MoS<sub>2</sub>/MnIn<sub>2</sub>S<sub>4</sub>**

## **CHAPTER 3: 2D MoS<sub>2</sub>/MnIn<sub>2</sub>S<sub>4</sub> hetero interface with improved interfacial charge carrier transfer for photocatalytic H<sub>2</sub>O<sub>2</sub> production**

---

The 2D MoS<sub>2</sub>/MnIn<sub>2</sub>S<sub>4</sub> heterostructures with varying concentrations of MnIn<sub>2</sub>S<sub>4</sub> nanosheets were synthesized using a straightforward hydrothermal method. Initially, a certain amount of 2D MoS<sub>2</sub> nanosheets was dispersed in deionized water and subjected to ultrasonication for 60 minutes to form a uniform suspension. Next, manganese chloride tetrahydrate (1 mmol), indium chloride tetrahydrate (2 mmol), and thiourea (5 mmol) were dissolved in deionized water with constant stirring on a magnetic stirrer. After one hour of stirring, the 2D MoS<sub>2</sub> suspension was added to the mixture and stirred for two more hours. The resulting mixture was then transferred to a Teflon-lined autoclave and heated at 210 °C for 24 hours. Once the reaction was complete, the samples were allowed to cool naturally to room temperature, then washed multiple times with water and ethanol and collected by centrifugation. The process produced 2D MoS<sub>2</sub>/MnIn<sub>2</sub>S<sub>4</sub> nanocomposites with varying MnIn<sub>2</sub>S<sub>4</sub> weight ratios, designated as MS/MnIS-*x*, where *x* corresponds to 10, 20, 40, 60, and 80, representing the weight percent of MnIn<sub>2</sub>S<sub>4</sub> relative to 2D MoS<sub>2</sub> in the reaction system.

### **3.2.4 Photocatalytic H<sub>2</sub>O<sub>2</sub> production**

The photocatalytic H<sub>2</sub>O<sub>2</sub> production experiment was carried out by dispersing 5 mg of the synthesized photocatalyst powder in 20 mL of a deionized water/ethanol mixture (95:5 vol%). The dispersion was facilitated through 10 minutes of ultrasonic bath treatment. Afterward, oxygen was bubbled through the solution and kept in the dark for 30 minutes to ensure equilibrium. The suspension was then exposed to irradiation from a solar simulator. Following one hour of photocatalytic reaction, a 2 mL aliquot was extracted, and the photocatalyst was separated from the reaction solution.

The concentration of H<sub>2</sub>O<sub>2</sub> was quantified using the iodometric method [86,114,115]. To the 2 mL aliquot (post photocatalyst removal), 2 mL of 0.1 M KI and 50

## CHAPTER 3: 2D MoS<sub>2</sub>/MnIn<sub>2</sub>S<sub>4</sub> hetero interface with improved interfacial charge carrier transfer for photocatalytic H<sub>2</sub>O<sub>2</sub> production

$\mu\text{L}$  of 0.01M ((NH<sub>4</sub>)<sub>6</sub>Mo<sub>7</sub>O<sub>24</sub>·4H<sub>2</sub>O) were added and thoroughly mixed. The reaction mixture was kept in the dark for 20 minutes to allow for a complete reaction. In this process, KI is oxidized by H<sub>2</sub>O<sub>2</sub>, releasing I<sub>2</sub>, which then reacts with excess I<sup>-</sup> (from KI) to form the yellow-colored triiodide anion (I<sub>3</sub><sup>-</sup>) through the reaction:  $\text{H}_2\text{O}_2 + 3\text{I}^- + 2\text{H}^+ \rightarrow \text{I}_3^-$ . The amount of I<sub>3</sub><sup>-</sup> generated is directly proportional to the concentration of H<sub>2</sub>O<sub>2</sub> in the sample. Finally, the absorbance of the resulting solution was measured using UV-vis spectroscopy, showing a characteristic intense absorption peak around 352 nm.

Furthermore, to achieve optimal yields in H<sub>2</sub>O<sub>2</sub> production, the experimental conditions, including pH, were systematically optimized. The primary reactive species generated during the photocatalytic process were identified using trapping experiments under irradiation. The contributions of electrons (e<sup>-</sup>), superoxide radicals ( $\cdot\text{O}_2^-$ ), and holes (h<sup>+</sup>) to H<sub>2</sub>O<sub>2</sub> production were assessed by introducing AgNO<sub>3</sub>, p-BQ, and EDTA-2Na as scavengers.

**Scheme 3.1** Schematic diagram illustrating the synthesis process of as-designed MS/MnIS-*x* heterostructure photocatalysts.

### 3.3 RESULTS AND DISCUSSION

### **CHAPTER 3: 2D MoS<sub>2</sub>/MnIn<sub>2</sub>S<sub>4</sub> hetero interface with improved interfacial charge carrier transfer for photocatalytic H<sub>2</sub>O<sub>2</sub> production**

---

Powder XRD was carried out to investigate the phase purity and crystal structures of the 2D MoS<sub>2</sub>, MnIn<sub>2</sub>S<sub>4</sub>, and MS/MnIS-*x* heterostructures. Figure 3.1 shows the corresponding XRD patterns of the various samples. The XRD pattern traced in purple is of the as-prepared 2D MoS<sub>2</sub> nanosheets. The observed diffraction peaks at two theta ( $2\theta$ ) values of 14.2°, 33.4°, and 58.8° can be uniquely attributed to the (002), (100), and (110) crystal planes of standard hexagonal MoS<sub>2</sub> (2H MoS<sub>2</sub>, JCPDS card No. 731508), respectively, revealing the high purity of the sample. There is an apparent broadening of all the peaks in the diffraction patterns, which suggests the nanoscales of the crystallites in different dimensions [113]. The red trace represents the diffraction pattern of the standard cubic structure MnIn<sub>2</sub>S<sub>4</sub> phase (JCPDS No. 85-1229). The characteristic peaks of MoS<sub>2</sub> at (002) and (110) were observed in all 2D MoS<sub>2</sub>/MnIn<sub>2</sub>S<sub>4</sub> heterostructures, confirming that the composite structure consists of hexagonal MoS<sub>2</sub> and cubic MnIn<sub>2</sub>S<sub>4</sub>. No diffraction peaks associated with impurities were detected, confirming the high purity of the synthesized heterostructure photocatalysts.

**Figure 3.1.** XRD patterns of 2D MoS<sub>2</sub>, MnIn<sub>2</sub>S<sub>4</sub>, and MS/MnIS-*x* heterostructure photocatalysts.

The optical properties of the 2D MoS<sub>2</sub> nanosheets, produced via liquid-phase ultrasonication, were examined using UV-visible absorbance spectrophotometry. A slight shift in the UV-visible spectral peak toward a lower wavelength (Figure 3.2a) suggests a change in the bandgap due to exfoliation. Additionally, the light absorbance in the visible region was significantly enhanced after exfoliation compared to bulk MoS<sub>2</sub>. Figure 3.2a (inset picture) indicates the successful and stable dispersion of exfoliated MoS<sub>2</sub> nanosheets.

Similarly, the optical characteristics of 2D MoS<sub>2</sub>, MnIn<sub>2</sub>S<sub>4</sub>, and the MS/MnIS-*x* heterostructure were explored through solid-state UV-Vis NIR analysis, as shown in Figure 3.2b. From the absorbance spectra, it is clear that 2D MoS<sub>2</sub> shows a strong visible light

### **CHAPTER 3: 2D MoS<sub>2</sub>/MnIn<sub>2</sub>S<sub>4</sub> hetero interface with improved interfacial charge carrier transfer for photocatalytic H<sub>2</sub>O<sub>2</sub> production**

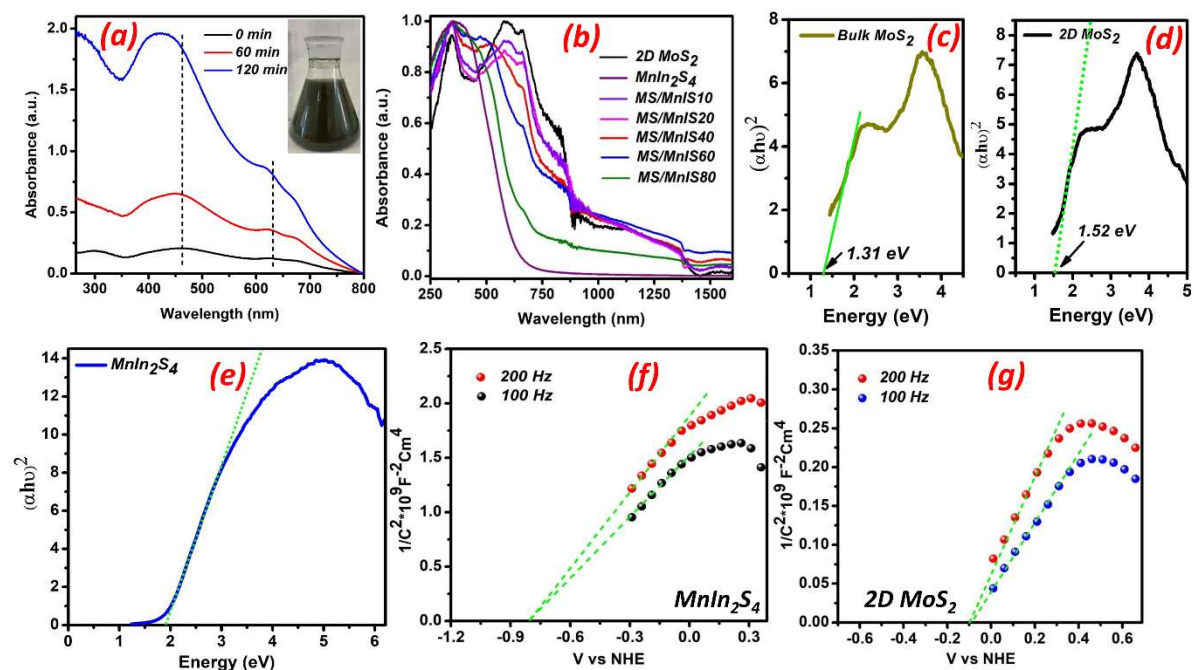

---

absorption band at a range of 300-1350 nm. Similarly, pristine MnIn<sub>2</sub>S<sub>4</sub> exhibited visible light absorption with a characteristic absorption edge near 680 nm. Compared to pristine MnIn<sub>2</sub>S<sub>4</sub>, the formation of the MS/MnIS-*x* heterostructure resulted in a significant redshift of the absorption edge, with strong absorption observed in the visible to NIR range from approximately 340 to 1350 nm. The DRS results demonstrated that the formation of 2D MoS<sub>2</sub>/MnIn<sub>2</sub>S<sub>4</sub> heterostructures allows for more efficient exploitation of solar energy. Further, the band gap energy (*E<sub>g</sub>*) of the 2D MoS<sub>2</sub>, MnIn<sub>2</sub>S<sub>4</sub>, was calculated by the Tauc plot method using Equation 3.1.

$$(\alpha h\nu)^{\frac{1}{n}} = A(h\nu - E_g) \dots \dots \dots (3.1)$$

Here *hν*, and *α* represent the photoelectron energy, and absorption coefficient, respectively. The measured band gap energies of 2D MoS<sub>2</sub> and MnIn<sub>2</sub>S<sub>4</sub> were 1.52 eV and 1.88 eV, respectively, as shown in Figure 3.2d and 3.2e. The calculated band gap of bulk MoS<sub>2</sub> (before exfoliation) are shown in Figure 3.2c. These results indicate that, after successful exfoliation into nanosheets, the band gap energy increased from 1.31 eV to 1.52 eV.

### CHAPTER 3: 2D MoS<sub>2</sub>/MnIn<sub>2</sub>S<sub>4</sub> hetero interface with improved interfacial charge carrier transfer for photocatalytic H<sub>2</sub>O<sub>2</sub> production

**Figure. 3.2.** (a) UV visible absorbance spectra of bulk MoS<sub>2</sub> and exfoliated MoS<sub>2</sub> nanosheets and inset Images of exfoliated MoS<sub>2</sub> nanosheets were captured 24 hours after ultrasonication bath treatment, confirming stable dispersion (b) Solid-state UV-DRS absorbance spectra of 2D MoS<sub>2</sub>, MnIn<sub>2</sub>S<sub>4</sub>, and MS/MnIS-*x* heterostructure photocatalysts (c) Tauc plot of bulk MoS<sub>2</sub> (un-exfoliated) (d, e) Tauc plot of 2D MoS<sub>2</sub> and MnIn<sub>2</sub>S<sub>4</sub>. Mott-Schottky plot of (f) MnIn<sub>2</sub>S<sub>4</sub> and (g) 2D MoS<sub>2</sub>.

Mott-Schottky (MS) measurements were carried out at 100 Hz and 200 Hz to investigate the band structure and semiconductor type. Figure 3.2 (f and g) shows the MS curves for 2D MoS<sub>2</sub> and MnIn<sub>2</sub>S<sub>4</sub> samples. Both 2D MoS<sub>2</sub> and MnIn<sub>2</sub>S<sub>4</sub> exhibited positive MS slopes, confirming their *n*-type semiconductor characteristics. The conduction band potentials were determined to be -0.1 V for 2D MoS<sub>2</sub> and -0.81 V for MnIn<sub>2</sub>S<sub>4</sub> versus NHE by fitting the  $1/C^2$  vs. potential plot. By combining the MS results with the energy band gaps of 2D MoS<sub>2</sub> and MnIn<sub>2</sub>S<sub>4</sub>, as determined by the Tauc plot, the valence band positions were calculated to be 1.42 V for 2D MoS<sub>2</sub> and 1.07 V for MnIn<sub>2</sub>S<sub>4</sub>, respectively, using the

### **CHAPTER 3: 2D MoS<sub>2</sub>/MnIn<sub>2</sub>S<sub>4</sub> hetero interface with improved interfacial charge carrier transfer for photocatalytic H<sub>2</sub>O<sub>2</sub> production**

---

formula  $E_{VB} = E_{CB} + Eg$  [29,116]. Here,  $E_{VB}$  represents the valence band edge position, and  $E_{CB}$  denotes the conduction band edge position. It is noteworthy that the CB potentials of MnIn<sub>2</sub>S<sub>4</sub> are more negative than the reduction potential of O<sub>2</sub>/•O<sub>2</sub><sup>-</sup> (-0.33 V vs. NHE) and O<sub>2</sub>/H<sub>2</sub>O<sub>2</sub> (0.68 V vs. NHE). This indicates that their reduction potential is sufficient to drive the formation of H<sub>2</sub>O<sub>2</sub>.

The morphologies and microstructures of MnIn<sub>2</sub>S<sub>4</sub>, 2D MoS<sub>2</sub>, and the MS/MnIS40 heterostructures were thoroughly characterized using SEM and TEM. The analysis revealed that both 2D MoS<sub>2</sub> and MnIn<sub>2</sub>S<sub>4</sub> exhibit a layered structure with lateral dimensions of several hundred nanometers, respectively. Figure 3.3 presents the SEM images of MnIn<sub>2</sub>S<sub>4</sub> and the MS/MnIS40. The pure MnIn<sub>2</sub>S<sub>4</sub> exhibits a distinctive nanoflower-like structure composed of small petal-like features, as shown in Figures 3.3a and 3.3b. Notably, these petal-like formations gradually orient themselves into a cohesive nanoflower morphology. This unique morphology is advantageous for photocatalytic H<sub>2</sub>O<sub>2</sub> production, as it provides many active sites for the reaction. Similarly, the SEM images of the MS/MnIS40 heterostructure (Figure 3.3c, d) illustrate the formation of small petal-like nanostructures of MnIn<sub>2</sub>S<sub>4</sub> embedded on the thin, layered 2D MoS<sub>2</sub> nanosheets. The corresponding SEM elemental mapping images confirm the uniform distribution of Mn, In, Mo, and S elements within the MS/MnIS40 heterostructure, indicating partial coverage of the 2D MoS<sub>2</sub> surface by MnIn<sub>2</sub>S<sub>4</sub>. However, as the MnIn<sub>2</sub>S<sub>4</sub> loading increases, excessive deposition leads to agglomeration, resulting in the formation of nanoflowers that entirely cover the 2D MoS<sub>2</sub> surface. Additionally, Figure 3.4 (a, b) presents the SEM images and elemental mapping for the MS/MnIS60 and MS/MnIS80 samples. No extra elements are detected in these samples, confirming the high purity and successful formation of the heterostructure in the synthesized materials.

### CHAPTER 3: 2D MoS<sub>2</sub>/MnIn<sub>2</sub>S<sub>4</sub> hetero interface with improved interfacial charge carrier transfer for photocatalytic H<sub>2</sub>O<sub>2</sub> production

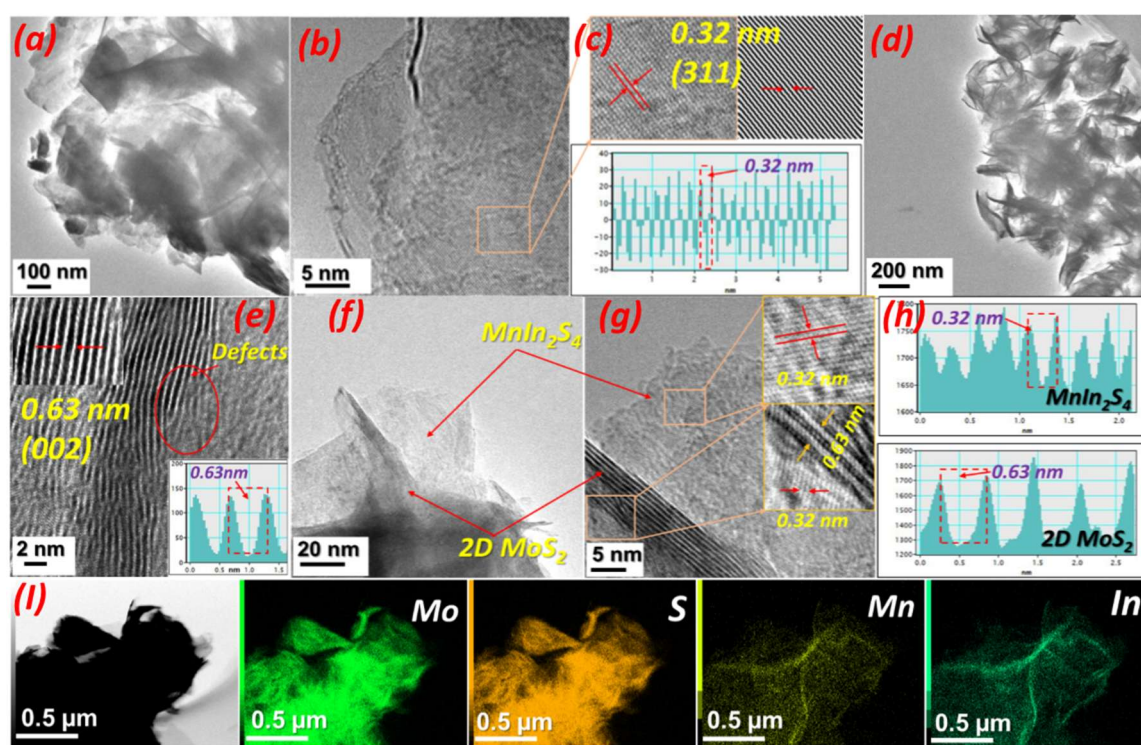

**Figure 3.3.** (a, b) SEM images of pristine MnIn<sub>2</sub>S<sub>4</sub> (c) SEM images of MS/MnIS40 heterostructure photocatalysts (d) SEM image with corresponding elemental maps (Mo, Mn, In, S) of MS/MnIS40 heterostructure photocatalysts.

**Figure 3.4.** (a, b) SEM images and elemental mapping of MS/MnIS60 and MS/MnIS80 heterostructure photocatalysts.

To further confirm the morphology and structure of 2D MoS<sub>2</sub>, MnIn<sub>2</sub>S<sub>4</sub>, and the MS/MnIS40 heterostructure were observed using TEM and high-resolution TEM (HRTEM). Notably, the TEM images of the MnIn<sub>2</sub>S<sub>4</sub> (Figure 3.5a) and 2D MoS<sub>2</sub> (Figure 3.5d) display layered structures with a nearly transparent appearance, consistent with the presence of ultrathin nanosheets. The inverse fast Fourier transform (IFFT) images and spectra of the HRTEM images of pristine MnIn<sub>2</sub>S<sub>4</sub>, as shown in Figure 3.5c, reveal distinct lattice fringes of 0.32 nm, corresponding to the (311) crystal plane of MnIn<sub>2</sub>S<sub>4</sub>, which is consistent with the intense peak observed in the XRD pattern (JCPDS No. 85-1229). Figure 3.5d reveals that the 2D MoS<sub>2</sub> consists of few-layered, curled nanosheets with a scattered orientation. As shown in Figure 3.5e, the interlayer spacing of 6.3 Å corresponds to the (002) planes of MoS<sub>2</sub>, verifying its hexagonal (2H) structure. These nanosheets exhibit higher crystallinity and a relatively intact layered configuration, which aligns well with the XRD results. The HRTEM images of the 2D MoS<sub>2</sub> nanosheets in Figure 3.5e reveal structural defects in the 2H MoS<sub>2</sub>, typically characterized by cracks and misaligned basal planes, as previously reported in the literature [113,117]. After forming the 2D MoS<sub>2</sub> and MnIn<sub>2</sub>S<sub>4</sub> heterostructures (MS/MnIS40), the structure exhibits an ultrathin nanosheet-on-nanosheet morphology (Figure 3.5 (f, g)) with a large contact surface. The IFFT images and spectra derived from the HRTEM image of the 2D/2D heterostructure (Figure 3.5h) reveal lattice fringes of MnIn<sub>2</sub>S<sub>4</sub> (0.32 nm) and 2D MoS<sub>2</sub> (0.63 nm), confirming strong interfacial contact between the two materials and the successful formation of the heterostructure. This extensive, intimate interface enables multiple pathways for carrier migration, enhancing charge separation efficiency. Furthermore, the elemental mapping

analysis of the selected region in Figure 3.5i for the MS/MnIS40 heterostructure demonstrates the well-defined spatial distribution of Mo, Mn, In, and S (Figure 3.5i). The electron microscopy results reveal a uniform and intimate coupling within the 2D structure of MoS<sub>2</sub>/MnIn<sub>2</sub>S<sub>4</sub>, which substantially increases the contact area. This expanded interface improves the separation of photoinduced charge carriers and facilitates more efficient electron transfer within the heterostructure, significantly enhancing photocatalytic activity [118].

**Figure 3.5.** TEM, HR-TEM, and IFFT images of (a, b, and c) pure MnIn<sub>2</sub>S<sub>4</sub> (d, e) 2D MoS<sub>2</sub> (f, g, and h) MS/MnIS40 heterostructure. (i) STEM elemental mapping of MS/MnIS40 heterostructure photocatalysts.

The X-ray photoelectron spectroscopy (XPS) analysis revealed the chemical states and interfacial interactions in the 2D MoS<sub>2</sub>, MnIn<sub>2</sub>S<sub>4</sub>, and MS/MnIS40 samples. The HR-XPS data was calibrated using the C 1s 284.8 eV binding energy [119]. The XPS survey spectrum in Figure 3.6a confirms the presence of Mo and S elements in MoS<sub>2</sub> and Mn, In,

### **CHAPTER 3: 2D MoS<sub>2</sub>/MnIn<sub>2</sub>S<sub>4</sub> hetero interface with improved interfacial charge carrier transfer for photocatalytic H<sub>2</sub>O<sub>2</sub> production**

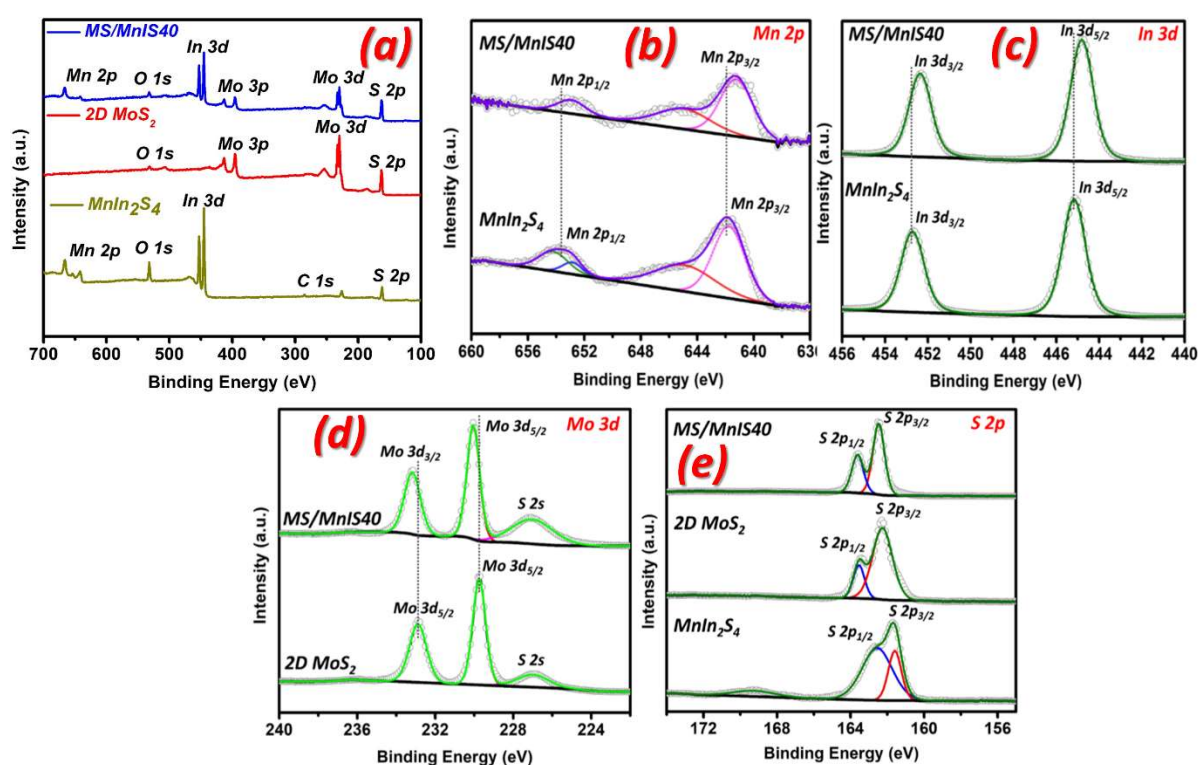

---

and S elements in MnIn<sub>2</sub>S<sub>4</sub>. Similarly, the survey spectrum of the MS/MnIS40 samples shows Mo, Mn, In, and S, further indicating the successful formation of heterostructures of 2D MoS<sub>2</sub> and MnIn<sub>2</sub>S<sub>4</sub>. The high resolution (HR) Mn 2p spectra of MnIn<sub>2</sub>S<sub>4</sub> (Figure 3.6b) show characteristic peaks at binding energies of 641.8 eV and 645.3 eV for Mn 2p<sub>3/2</sub> and 652.8 eV and 654.1 eV for Mn 2p<sub>1/2</sub>. These peaks are attributed to the Mn<sup>2+</sup> and Mn<sup>4+</sup> oxidation states [112]. In the Mn 2p spectra of the MS/MnIS40 heterostructure (Figure 3.6b), the Mn 2p<sub>3/2</sub> and Mn 2p<sub>1/2</sub> peaks are slightly shifted towards lower binding energies. Figure 3.6c shows the In 3d spectra for both MnIn<sub>2</sub>S<sub>4</sub> and MS/MnIS40, where the binding energies of the In 3d peaks at 445.1 eV (In 3d<sub>5/2</sub>) and 452.7 eV (In 3d<sub>3/2</sub>) confirm the +3 oxidation state of In in MnIn<sub>2</sub>S<sub>4</sub>. Compared to pure MnIn<sub>2</sub>S<sub>4</sub>, the In 3d XPS peaks in the MS/MnIS40 heterostructures also shift towards lower binding energies.

The Mo 3d spectrum (Figure 3.6d) exhibits two distinct peaks at 229.7 eV and 232.9 eV, corresponding to the binding energies of Mo 3d<sub>5/2</sub> and Mo 3d<sub>3/2</sub>, associated with the 2H phase of MoS<sub>2</sub>. These findings confirm that Mo in MoS<sub>2</sub> is in the +4 oxidation state. An additional peak observed at a binding energy of 226.8 eV corresponds to the S 2s state, indicating the interaction between S and Mo. Compared to 2D MoS<sub>2</sub>, the characteristic Mo 3d peaks of MS/MnIS40 shift slightly to higher binding energies. Conversely, the Mn 2p and In 3d peaks in MnIn<sub>2</sub>S<sub>4</sub> shift to lower binding energies upon forming MS/MnIS40 heterostructure, suggesting a strong interaction between 2D MoS<sub>2</sub> and MnIn<sub>2</sub>S<sub>4</sub> [120]. A shift to lower binding energy indicates an increase in electron cloud density, while a shift to higher binding energy implies a decrease in electron cloud density. Consequently, the binding energy shifts observed in the XPS reveal the direction of electron transfer from 2D MoS<sub>2</sub> to MnIn<sub>2</sub>S<sub>4</sub> in the MS/MnIS40 heterostructure system [49,121–123].

## CHAPTER 3: 2D MoS<sub>2</sub>/MnIn<sub>2</sub>S<sub>4</sub> hetero interface with improved interfacial charge carrier transfer for photocatalytic H<sub>2</sub>O<sub>2</sub> production

Figure 3.6e displays the HR S 2p spectra of MnIn<sub>2</sub>S<sub>4</sub>, 2D MoS<sub>2</sub>, and MS/MnIS40 heterostructure. The S 2p spectrum displays two distinct peaks at 162.2 eV for S 2p<sub>3/2</sub> and 163.5 eV for S 2p<sub>1/2</sub>, corresponding to the binding energies of S<sup>2-</sup> ions in MoS<sub>2</sub> [124]. The S 2p binding energies of MnIn<sub>2</sub>S<sub>4</sub> were detected at 161.6 eV for S 2p<sub>3/2</sub> and 162.5 eV for S 2p<sub>1/2</sub>, respectively. The small peak at a binding energy of 168.9 eV is attributed to sulfate species formed by the oxidation of sulfur in air [125].

**Figure 3.6.** (a) XPS spectra of 2D MoS<sub>2</sub>, MnIn<sub>2</sub>S<sub>4</sub>, and MS/MnIS40 (b) Mn 2p (c) In 3d (d) Mo 3d (e) S 2p.

A photoluminescence (PL) study of the photocatalytic material gives insights into photo-induced charge carriers' migration, transfer, and separation efficiency. Typically, a decrease in the PL emission intensity corresponds to a reduction in the charge carrier recombination rate, indicating enhanced separation of photo-generated electron-hole pairs

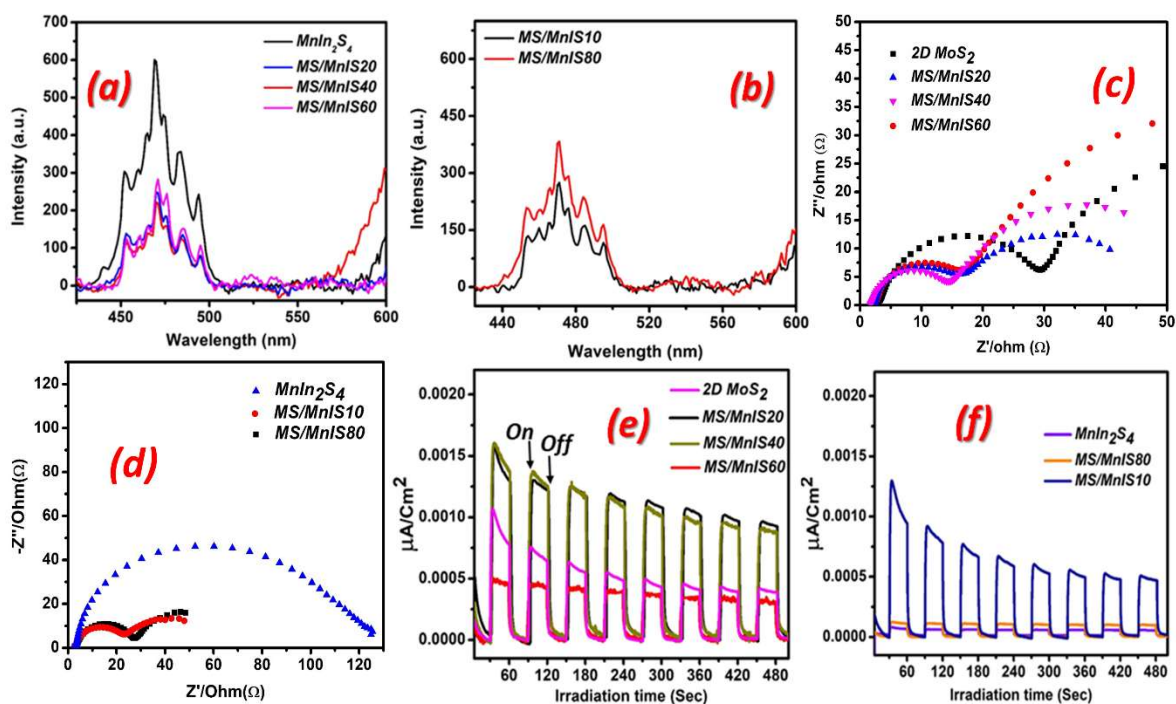

### **CHAPTER 3: 2D MoS<sub>2</sub>/MnIn<sub>2</sub>S<sub>4</sub> hetero interface with improved interfacial charge carrier transfer for photocatalytic H<sub>2</sub>O<sub>2</sub> production**

---

[114]. The PL emission spectra of pristine MnIn<sub>2</sub>S<sub>4</sub> and MS/MnIS-*x*, excited at 340 nm at room temperature, are shown in Figure 3.7a. The PL spectra of MS/MnIS10 and MS/MnIS80 are shown in the Figure 3.7b. A prominent emission peak centered at 450 nm is observed for the as-prepared photocatalysts. In contrast, the MS/MnIS40 heterostructure exhibits the lowest PL intensity among the other photocatalysts. This suggests that loading 40% MnIn<sub>2</sub>S<sub>4</sub> onto 2D MoS<sub>2</sub> enhances the separation of electron-hole pairs on the catalyst's surface. This enhancement likely contributes to the superior photocatalytic performance of the MS/MnIS40 heterostructure toward the oxygen reduction reaction (ORR). The primary reason is the reduced recombination rate of photo-generated electrons, which allows them to migrate efficiently to the surface of MnIn<sub>2</sub>S<sub>4</sub>, thereby enhancing the photo-reduction process. Furthermore, electrochemical impedance spectroscopy (EIS) was conducted to assess the interfacial charge transfer behavior of the prepared photocatalysts. Figure 3.7c presents the Nyquist plots of the 2D MoS<sub>2</sub> and MS/MnIS-*x* heterostructure systems. Figure 3.7d shows the Nyquist plot of MnIn<sub>2</sub>S<sub>4</sub>, MS/MnIS10, and MS/MnIS80 photocatalysts. As illustrated, the MS/MnIS40 system exhibits the smallest arc diameter, signifying reduced charge transfer resistance and impedance, suggesting improved charge migration [126]. In the MS/MnIS40 heterojunction, the heterostructure formation is well-balanced with a proper interface, ensuring effective electron transport from 2D MoS<sub>2</sub> to MnIn<sub>2</sub>S<sub>4</sub> while minimizing charge recombination. In contrast, lower MnIn<sub>2</sub>S<sub>4</sub> loadings (10 wt.% and 20 wt.%) result in insufficient heterojunction formation, leading to higher recombination losses. On the other hand, excessive MnIn<sub>2</sub>S<sub>4</sub> content (60 wt% and 80 wt%) causes nanosheet agglomeration, which not only covers the active sites on the 2D MoS<sub>2</sub> surface but also leads to charge accumulation, ultimately increasing resistance. Similar results were observed for these materials in the transient photocurrent responses (Figure 3.7e, f). The charge separation process is reflected in the transient photocurrent, as shown by the

### CHAPTER 3: 2D MoS<sub>2</sub>/MnIn<sub>2</sub>S<sub>4</sub> hetero interface with improved interfacial charge carrier transfer for photocatalytic H<sub>2</sub>O<sub>2</sub> production

chronoamperometry. A significant spike in current occurs immediately upon light exposure, followed by a rapid decline when the light is turned off (Figure 3.7e). Notably, the MS/MnIS40 heterostructure photocatalyst exhibits a significantly higher photocurrent density compared to the other prepared photocatalysts. The photocurrent response of MnIn<sub>2</sub>S<sub>4</sub>, MS/MnIS10, and MS/MnIS80 are given in Figure 3.7f. The combined observations from PL, EIS, and photocurrent experiments demonstrate that the MS/MnIS40 heterostructure can serve as an efficient photocatalyst, exhibiting enhanced photocatalytic H<sub>2</sub>O<sub>2</sub> production.

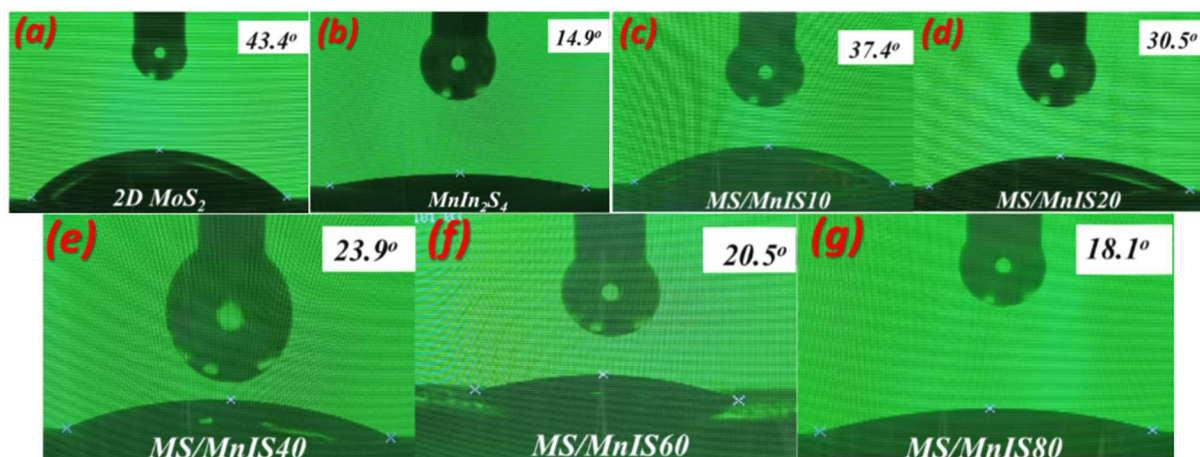

**Figure 3.7.** (a, b) PL spectra of MnIn<sub>2</sub>S<sub>4</sub> and MS/MnIS-x heterostructure photocatalysts (c-f) Nyquist plot and photocurrent studies of 2D MoS<sub>2</sub> and MS/MnIS-x heterostructure photocatalysts.

To investigate the impact of photocatalyst surface properties on its activity, contact angle measurements were performed to assess the hydrophilic characteristics of

## CHAPTER 3: 2D MoS<sub>2</sub>/MnIn<sub>2</sub>S<sub>4</sub> hetero interface with improved interfacial charge carrier transfer for photocatalytic H<sub>2</sub>O<sub>2</sub> production

photocatalysts. These experiments were carried out under similar conditions, as a reactant of 5 % (vol) ethanol-containing water was used. After 2 seconds of contact with water/ethanol mixture droplets, the contact angle of 2D MoS<sub>2</sub>, MnIn<sub>2</sub>S<sub>4</sub>, MS/MnIS10, MS/MnIS20, MS/MnIS40, MS/MnIS60, and MS/MnIS80 are 43.4°, 14.9°, 37.4°, 30.5°, 23.9°, 20.5° and 18.1°; results confirmed its hydrophilic nature (Figure 3.8). A smaller contact angle signifies better wetting of the photocatalyst particle surface by the solvent molecules. It also implies longer residence times for solvent molecules from the water/ethanol mixture, facilitating better contact between the photocatalyst particles and reactants [127]. Additionally, the hydrophilic surface improves the uniform dispersion of the photocatalyst within the reaction system, leading to increased reaction rates and selectivity.

### 3.3.1. Photocatalytic H<sub>2</sub>O<sub>2</sub> production

The photocatalytic activities of 2D MoS<sub>2</sub>, MnIn<sub>2</sub>S<sub>4</sub>, and MS/MnIS-*x* for H<sub>2</sub>O<sub>2</sub> production were evaluated under various controlled conditions at room temperature and

### **CHAPTER 3: 2D MoS<sub>2</sub>/MnIn<sub>2</sub>S<sub>4</sub> hetero interface with improved interfacial charge carrier transfer for photocatalytic H<sub>2</sub>O<sub>2</sub> production**

---

atmospheric pressure. Initially, H<sub>2</sub>O<sub>2</sub> production was tested without a catalyst or light irradiation. Under these conditions, no H<sub>2</sub>O<sub>2</sub> was detected, confirming that the H<sub>2</sub>O<sub>2</sub> production reaction at room temperature is driven by solar light in the presence of photocatalysts. Figure 3.9a illustrates the H<sub>2</sub>O<sub>2</sub> production rates for different photocatalysts in O<sub>2</sub>-bubbled water at pH 3. The MS/MnIS-*x* heterostructure photocatalysts demonstrated significant H<sub>2</sub>O<sub>2</sub> formation compared to pristine 2D MoS<sub>2</sub> and MnIn<sub>2</sub>S<sub>4</sub>. Among the various MnIn<sub>2</sub>S<sub>4</sub> loadings, the 40 wt% loading onto 2D MoS<sub>2</sub> achieved an appreciable H<sub>2</sub>O<sub>2</sub> production rate of 240.2 μmol g<sup>-1</sup>h<sup>-1</sup>. However, further increasing the MnIn<sub>2</sub>S<sub>4</sub> loading onto the 2D MoS<sub>2</sub> resulted in a decline in H<sub>2</sub>O<sub>2</sub> production, likely due to excessive 2D MoS<sub>2</sub> active surface coverage. Moreover, the excess loading caused agglomeration of the nanosheets, as confirmed by the SEM image and elemental mapping of MS/MnIS60 and MS/MnIS80. This excessive coverage impairs visible light absorption and hinders efficient interfacial charge transfer, as evidenced by the EIS and PL results.

In contrast, when ethanol was introduced into the reaction mixture as a sacrificial agent, the photocatalytic H<sub>2</sub>O<sub>2</sub> production rate was improved, as shown in Figure 3.9a. Figure 3.9b displays the time-dependent curve of photocatalytic H<sub>2</sub>O<sub>2</sub> production of different photocatalysts. This enhancement confirms the oxidation of ethanol by the photogenerated holes. The best-performing photocatalyst, MS/MnIS40, achieved an impressive H<sub>2</sub>O<sub>2</sub> production rate of 606.7 μmol g<sup>-1</sup> h<sup>-1</sup>, whereas pristine 2D MoS<sub>2</sub> and MnIn<sub>2</sub>S<sub>4</sub> exhibited only 147.4 μmol g<sup>-1</sup> h<sup>-1</sup> and 121.5 μmol g<sup>-1</sup> h<sup>-1</sup>, respectively. This corresponds to an approximately 4.2-fold increase compared to pristine 2D MoS<sub>2</sub> and a 5-fold increase compared to MnIn<sub>2</sub>S<sub>4</sub> alone. Notably, the H<sub>2</sub>O<sub>2</sub> generation rate of our MS/MnIS40 surpassed that of recently reported heterostructure-based photocatalysts (Figure 3.9i and Table 3.1).

### **CHAPTER 3: 2D MoS<sub>2</sub>/MnIn<sub>2</sub>S<sub>4</sub> hetero interface with improved interfacial charge carrier transfer for photocatalytic H<sub>2</sub>O<sub>2</sub> production**

---

The photocatalytic H<sub>2</sub>O<sub>2</sub> production activity of the best catalyst (MS/MnIS40) was further evaluated at different pH levels (1.5, 3, 5, and 7). The pH-dependent experiments showed that the activity followed the trend: pH 3 > pH 1.5 > pH 5 > pH 7. At pH 3, a significantly enhanced H<sub>2</sub>O<sub>2</sub> production rate of 606.7 μmol g<sup>-1</sup>h<sup>-1</sup> was achieved (Figure 3.9c), suggesting that protonation-induced ionic species contribute to the improved activity [128]. At a low pH of 1.5, the solution provides an excess of protons (H<sup>+</sup>) in the reaction medium, which promotes the oxidation of H<sub>2</sub>O<sub>2</sub> to water (H<sub>2</sub>O<sub>2</sub> + 2H<sup>+</sup> + 2e<sup>-</sup> → 2H<sub>2</sub>O), thereby reducing the overall H<sub>2</sub>O<sub>2</sub> yield. Conversely, at pH 5 and 7, the lower availability of protons in the solution results in decreased H<sub>2</sub>O<sub>2</sub> formation. Moreover, at a higher pH solution, •O<sub>2</sub><sup>-</sup> becomes unstable, and H<sub>2</sub>O<sub>2</sub> breaks down more quickly, further lowering its production. Hence, pH 3 was identified as the optimum pH for H<sub>2</sub>O<sub>2</sub> production [86,129,130].

To investigate the effect of the heterostructure in MS/MnIS40, control experiments using a physical blend of 60% 2D MoS<sub>2</sub> and 40% MnIn<sub>2</sub>S<sub>4</sub> photocatalyst were conducted under optimal H<sub>2</sub>O<sub>2</sub> production conditions (Figure 3.9d). Under these conditions, the H<sub>2</sub>O<sub>2</sub> production rate was only 188.4 μmol g<sup>-1</sup> h<sup>-1</sup>, approximately 3.3 times lower than the best photocatalyst (MS/MnIS40). These results confirm that the proper formation of the heterostructure enhances visible light absorption and suppresses charge carrier recombination, leading to higher photocatalytic activity.

To gain further insight into the photocatalytic oxygen reduction reaction (ORR) pathway for H<sub>2</sub>O<sub>2</sub> production by the MS/MnIS40 photocatalyst, control experiments with various scavengers were conducted. The photocatalytic performance of MS/MnIS40 was also evaluated under argon (Ar) atmosphere. When the reaction systems were purged with Ar, the H<sub>2</sub>O<sub>2</sub> concentration dropped by 82%, demonstrating that O<sub>2</sub> plays a crucial role in

### **CHAPTER 3: 2D MoS<sub>2</sub>/MnIn<sub>2</sub>S<sub>4</sub> hetero interface with improved interfacial charge carrier transfer for photocatalytic H<sub>2</sub>O<sub>2</sub> production**

---

the photocatalytic process, with H<sub>2</sub>O<sub>2</sub> predominantly formed via the ORR. Interestingly, 18% of the H<sub>2</sub>O<sub>2</sub> concentration was retained even under the Ar atmosphere, suggesting that the ORR process subsequently consumes the O<sub>2</sub> generated from water oxidation to produce H<sub>2</sub>O<sub>2</sub> (Figure 3.9d). Two potential routes have been reported for synthesizing H<sub>2</sub>O<sub>2</sub> from O<sub>2</sub> via a 2e<sup>-</sup> redox process: a two-step ORR process involving <sup>•</sup>O<sub>2</sub><sup>-</sup> as an intermediate species and a direct 2e<sup>-</sup> ORR process. To clarify the exact pathway, a <sup>•</sup>O<sub>2</sub><sup>-</sup> scavenger test was conducted using p-BQ. As shown in Figure 3.9e, the scavenger experiment with p-BQ indicated the formation of <sup>•</sup>O<sub>2</sub><sup>-</sup> during the photocatalytic H<sub>2</sub>O<sub>2</sub> production pathway, as adding p-BQ reduced H<sub>2</sub>O<sub>2</sub> production by 65%. This result confirms that O<sub>2</sub> is reduced to form H<sub>2</sub>O<sub>2</sub> through the <sup>•</sup>O<sub>2</sub><sup>-</sup> intermediate via a two-step process [131]. Further validation of <sup>•</sup>O<sub>2</sub><sup>-</sup> involvement was conducted using the NBT test. As shown in Figure 3.9h, NBT is selectively reduced by <sup>•</sup>O<sub>2</sub><sup>-</sup>, forming formazan. This reduction is evidenced by decreased NBT absorption intensity with prolonged illumination. The detailed experimental protocol of NBT experiments is provided in Chapter 2. Furthermore, adding AgNO<sub>3</sub> confirmed that photo-generated electrons play a crucial role in the photocatalytic process, significantly reducing H<sub>2</sub>O<sub>2</sub> production. Similarly, introducing EDTA-2Na as a hole (h<sup>+</sup>) scavenger resulted in approximately a 76% reduction in H<sub>2</sub>O<sub>2</sub> production compared to the case of no scavenger, highlighting the involvement of h<sup>+</sup> in the photocatalytic reaction. This result suggests that <sup>•</sup>O<sub>2</sub><sup>-</sup> radicals, e<sup>-</sup>, and h<sup>+</sup> play a major role in photocatalytic H<sub>2</sub>O<sub>2</sub> production (Figure 3.9e).

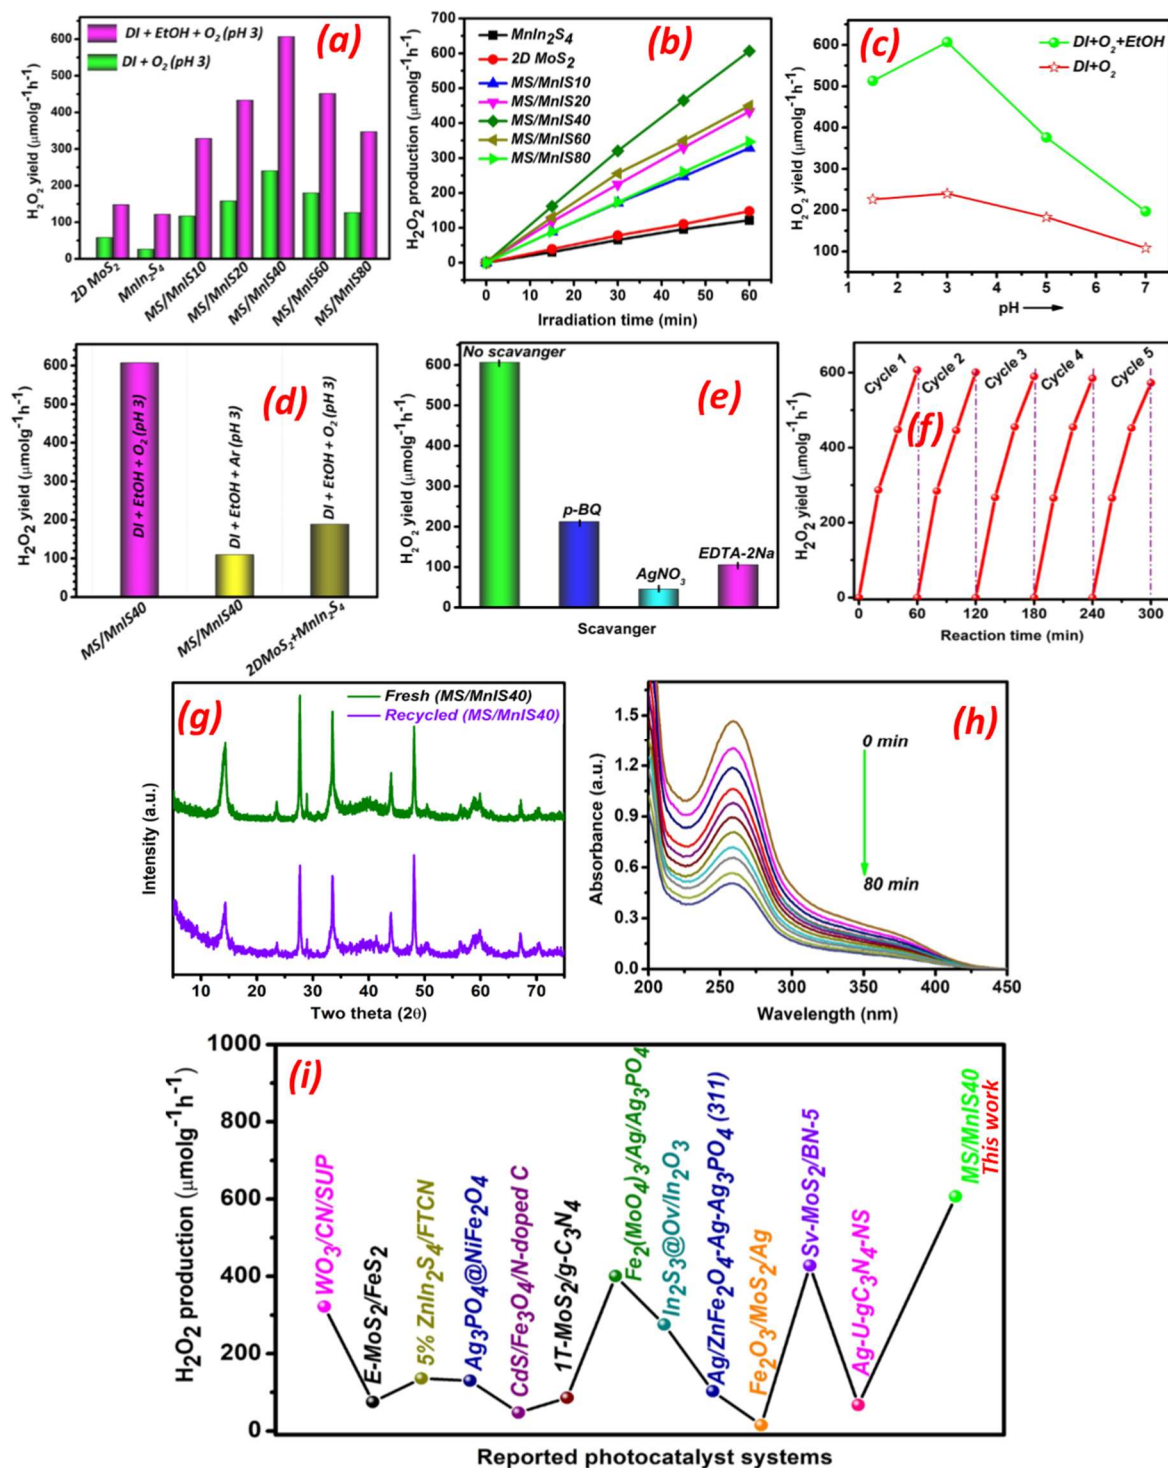

The photostability of photocatalytic materials is a critical factor influencing H<sub>2</sub>O<sub>2</sub> production efficiency. To evaluate this, the recyclability of the MS/MnIS40 photocatalyst for H<sub>2</sub>O<sub>2</sub> production was tested over five cycles under identical experimental conditions. After each cycle, the photocatalyst was recovered by centrifugation, rinsed with ethanol,

### **CHAPTER 3: 2D MoS<sub>2</sub>/MnIn<sub>2</sub>S<sub>4</sub> hetero interface with improved interfacial charge carrier transfer for photocatalytic H<sub>2</sub>O<sub>2</sub> production**

---

and dried at 60°C for five hours to assess its reusability. The dried photocatalyst was then reused in subsequent cycles. Figure 3.9f illustrates the H<sub>2</sub>O<sub>2</sub> production activity of the MS/MnIS40 photocatalyst over five reuse cycles. After five cycles, the MS/MnIS40 heterostructure demonstrated remarkable stability, with H<sub>2</sub>O<sub>2</sub> production remaining nearly unchanged and only a slight 7.8% decrease in H<sub>2</sub>O<sub>2</sub> formation efficiency. This indicates that the heterostructure maintains its photocatalytic activity well, which is crucial for practical applications. Moreover, we performed XRD and XPS measurements of the recycled photocatalyst, as shown in Figure 3.9g and Figure 3.10. The XRD patterns and XPS spectra of MS/MnIS40 before and after the fifth cycle of the photocatalytic reaction show no noticeable changes, indicating that the crystal structure and chemical states remained stable throughout the recycling process. These findings strongly confirm that the MS/MnIS40 heterostructure exhibits excellent photochemical stability and reusability, which is advantageous for long-term use and continuous operation in photocatalytic H<sub>2</sub>O<sub>2</sub> production systems.

### 3.4 Photocatalytic Mechanism

### CHAPTER 3: 2D MoS<sub>2</sub>/MnIn<sub>2</sub>S<sub>4</sub> hetero interface with improved interfacial charge carrier transfer for photocatalytic H<sub>2</sub>O<sub>2</sub> production

---

The photocatalytic H<sub>2</sub>O<sub>2</sub> production of as-prepared photocatalysts performance is presented in Figure 3.9 (a, b). Among them, MS/MnIS40 exhibits the highest photocatalytic activity compared to the other catalysts. Based on the experimental data, a photocatalytic H<sub>2</sub>O<sub>2</sub> production mechanism is proposed, as illustrated in Figure 3.11. The combination of 2D MoS<sub>2</sub> and MnIn<sub>2</sub>S<sub>4</sub> likely forms a Z-scheme heterojunction, as suggested by the Mott-Schottky and scavenger tests. Upon light irradiation of the MS/MnIS40 photocatalyst, photogenerated electrons accumulate in the CB of MnIn<sub>2</sub>S<sub>4</sub>, which has a more negative E<sub>CB</sub> potential at -0.81 eV (vs. V NHE), closely aligning with the reduction potential of O<sub>2</sub> at -0.33 eV (vs. V NHE). The negative potential of MnIn<sub>2</sub>S<sub>4</sub> CB and the O<sub>2</sub>/•O<sub>2</sub><sup>-</sup> couple facilitates rapid electron transfer, promoting the two-step one electron O<sub>2</sub> reduction necessary for H<sub>2</sub>O<sub>2</sub> generation (Equations 3.2 and 3.3). The significant reduction in H<sub>2</sub>O<sub>2</sub> yield in the presence of p-BQ and NBT experiments confirms that •O<sub>2</sub><sup>-</sup> is the primary active species. This suggests that H<sub>2</sub>O<sub>2</sub> is produced through the further conversion of •O<sub>2</sub><sup>-</sup> radicals, generated by the reduction of O<sub>2</sub> at -0.33 eV (vs. V NHE). Simultaneously, the photo-generated holes in the VB of 2D MoS<sub>2</sub> oxidize water molecules, producing O<sub>2</sub> and H<sup>+</sup> (Equation 3.4), as the VB potential of 2D MoS<sub>2</sub> (+1.42 V vs. NHE) is more positive than the H<sub>2</sub>O/O<sub>2</sub> potential (+1.23 V vs. NHE). Control experiments under ‘Ar’ purging showed that 18% of the H<sub>2</sub>O<sub>2</sub> concentration was retained even in the absence of external O<sub>2</sub>, suggesting that O<sub>2</sub> is generated from water oxidation. Moreover, the addition of ethanol significantly enhances H<sub>2</sub>O<sub>2</sub> production by facilitating its activation, as photo-generated holes are efficiently consumed in the oxidation of ethanol. This reaction also provides H<sup>+</sup> ions, which later react with •O<sub>2</sub><sup>-</sup> to form H<sub>2</sub>O<sub>2</sub> (Equation 3.5) [143]. These factors are crucial for optimizing the photocatalytic ORR process to boost H<sub>2</sub>O<sub>2</sub> production.

## CHAPTER 3: 2D MoS<sub>2</sub>/MnIn<sub>2</sub>S<sub>4</sub> hetero interface with improved interfacial charge carrier transfer for photocatalytic H<sub>2</sub>O<sub>2</sub> production

**Figure 3.11** Possible mechanism of the photocatalytic H<sub>2</sub>O<sub>2</sub> generation on 2D MoS<sub>2</sub>/MnIn<sub>2</sub>S<sub>4</sub> photocatalyst.

### 3.5 Conclusions

In conclusion, composite photocatalysts with MnIn<sub>2</sub>S<sub>4</sub> nanostructures embedded on ultrathin 2D MoS<sub>2</sub> nanosheets have been fabricated for solar-driven H<sub>2</sub>O<sub>2</sub> production using a facile two-step hydrothermal method. It was observed that the optimal loading of MnIn<sub>2</sub>S<sub>4</sub> partially covers the 2D MoS<sub>2</sub> nanosheets, enhancing light absorption and providing more active sites. This leads to improved charge carrier separation and accelerated electron transfer, resulting in enhanced photocatalytic H<sub>2</sub>O<sub>2</sub> production. However, excessive loading of MnIn<sub>2</sub>S<sub>4</sub> covers the surface-active sites of MoS<sub>2</sub> and blocks light absorption, leading to poor interfacial charge carrier separation and reduced photocatalytic activity. Moreover, the poor H<sub>2</sub>O<sub>2</sub> production activity observed in physical blending experiments (2D MoS<sub>2</sub> + MnIn<sub>2</sub>S<sub>4</sub>) confirms that when proper heterostructures are formed, the MS/MnIS40 photocatalyst exhibits excellent H<sub>2</sub>O<sub>2</sub> production activity, approximately 3.3 times higher

### **CHAPTER 3: 2D MoS<sub>2</sub>/MnIn<sub>2</sub>S<sub>4</sub> hetero interface with improved interfacial charge carrier transfer for photocatalytic H<sub>2</sub>O<sub>2</sub> production**

---

than that of the physically blended mixtures. This demonstrates that the formation of an intimately connected/contacted heterostructure effectively inhibits charge recombination and accelerates charge transfer. The microscopy characterization results reveal a strong interfacial interaction between the components of 2D MoS<sub>2</sub> and MnIn<sub>2</sub>S<sub>4</sub>. The controlled radical trapping studies confirmed that H<sub>2</sub>O<sub>2</sub> generation preferably occurred via a dual-step, one-electron O<sub>2</sub> reduction pathway. This study can inspire the exploration and development of effective noble-metal-free semiconductor heterostructure photocatalysts for solar-driven H<sub>2</sub>O<sub>2</sub> generation.
